

An extraction method for glacial lakes based on Landsat-8 imagery using an improved U-Net network

Yi He, Sheng Yao, Wang Yang, Haowen Yan*, Lifeng Zhang, Zhiqing Wen, Yali Zhang and Tao Liu

Abstract—Remote sensing monitoring of glacial lakes is an indispensable tool for identifying and preventing glacial lake disasters. At present, existing extraction methods of glacial lakes based on Landsat remote sensing image have achieved remarkable results, but the algorithms used lack the ability to analyse glacial lake spectral and shape and texture features, and require manual design parameters to fine-tune the automation of the algorithm. As a result, it cannot mine depth features of glacier lakes in remote sensing images accurately enough. To address these challenges, this study designed a self-attention mechanism module U-Net network that enhances the propagation of features, reduces information loss, strengthens the weight of glacial lake areas, restrains the weight of irrelevant features, reduces the influence of low image contrast on the model and deals with the variety of pixel categories in glacial lakes. These features improve the performance of the model. Based on Landsat-8 images, we first extracted glacial lakes in large-scale alpine areas using a U-Net network model. To make it a self-attention U-Net network, we introduced the attention mechanism into the step connection part of the U-Net network to adjust feature weight, focus on learning glacial lake features and strengthen the network to extract the glacial lake features. Finally, we selected the combination of band 3, 5 and 6 and all bands of Landsat-8 images using the self-attention U-Net network to extract glacial lakes in the study area and compared and analysed the extraction results. Experimental results and analyses revealed that the proposed method can effectively segment glacial lakes from Landsat-8 remote sensing images. Its effectiveness was proven by different evaluation indices. Compared to a standard U-Net network, the true positive (TP) for the combination of 3, 5 and 6 bands increased by 15.95% and for all bands by 5.79%. The Area Under Curve (AUC) for the whole study area reached 85.03% for all bands. The improved U-Net network can thus meet the real-time needs of glacial lake disaster information acquisition.

(Corresponding author: Haowen Yan)

water in moraine ridge depressions [1]. Glacial lakes are incubators of alpine glacial disasters and are important in the study of mountain disasters [2]. Many glacial lake collapse events have occurred in recent years, resulting in significant losses in life and property [3]. Real-time monitoring of glacial lakes is therefore essential. Glacial lakes are a special kind of lake with diverse features found at high altitudes. The geographic information contained in optical remote sensing images is complex, and the sensors of optical remote sensing satellites have multi-band data, which are affected by different topographies and also carry complex semantic information [4]. In remote sensing images, glacial lakes can appear similar to some ground features (such as mountain shadows, melting glaciers, etc.), so it is difficult to extract large-scale remote sensing data on glacial lakes accurately.

At present, remote sensing extraction methods of glacial lake boundary information mainly include manual digitisation, spectral information, traditional machine learning and image semantic segmentation. The manual digitisation method is highly accurate but time- and labour-consuming, as well as inefficient, so it is suitable only for small-scale glacial lake information extraction [5]-[6]. The representative algorithms of the spectral information method include threshold and water body index methods, which are usually used together. The idea is to use the normalised water body index (Normalised Difference Water Index, NDWI) to set the global threshold, eliminate non-glacial lake information, and extract the glacial lake information. The spectral information method is simple and effective, but it is suitable only for small areas, because the spectral characteristics of glacial lakes and some ground objects (such as mountain shadows, melting glaciers, etc.) in large areas are similar [7].

The representative algorithms of traditional machine learning include decision trees and neural networks. Decision tree and neural network methods are suitable for areas with prior knowledge, which limits their universal application [8]-[13]. Image semantic segmentation methods include object-oriented

segmentation and distributed iteration. The image semantic segmentation method can accurately extract glacial lake boundaries by using image features, but it requires post-processing operations, and the segmentation scale of the area where glacial lakes are located and the size of glacial lakes vary, which also limits the wide application of the method [14]-[15]. Existing glacial lake extraction algorithms generally lack the ability to analyse the spectrum, shape, texture and other features of glacial lakes because of the differences in pixel spectra between glacial lakes, which makes it difficult to extract glacial lake data on a large-scale. The algorithms also require more manual design parameters to realise their automation. Deep learning is an emerging multi-layer neural network learning algorithm that can extract intrinsic and deep features [16]. Without manual intervention, advanced features can be obtained from original features to improve the accuracy of classification [17]-[19]. Deep learning algorithms have been widely used in the study of remote sensing image classification and have achieved remarkable results [17],[19],[20]-[23]. Compared with conventional methods, deep learning can better deal with the complex features of remote sensing images and has stronger autonomous learning ability [24].

Deep full convolutional neural (FCN) networks show advantages in the field of image semantic segmentation, and uses its code-decoding structure to segment ground objects and achieves good results [25]-[26]. On the basis of FCN, Ronneberger et al. [27] proposed a U-shaped symmetric network (U-Net), which can integrate low and high dimensional features, which greatly improves segmentation accuracy. U-net networks have been widely applied in the classification of remote sensing images [28]-[29]. Later, scholars extracted water bodies using a U-Net network and achieved good results, but it underperformed when segmentation targets were very small [30]-[31]. When lake and mountain areas account for only a small fraction of the cutting area, traditional networks run into a limitation, which is that the U-Net skip connection directly to the deep features of shallow features of encoder and decoder combining prone to semantic gap [32]. This study used jump connection module replacement parts for the space attention mechanism. This way, the jump part of the network can focus on the input feature subset and select specific and noteworthy input, thus solving the problem of overloading original information and the semantic gap problem of the U-Net jump part due to the combination of features of different dimensions. Thus, it improves the classification accuracy of small targets. We define the network designed in this study as a self-attention U-Net.

In this study, 11 bands of Landsat-8 were used to extract a glacial lake. NDWI and normalised differential snow index (NDSI) are standard methods of extracting water. The 3, 5 and 6 bands of Landsat-8 image are sensitive to water, so this experiment also tried to combine these bands to extract the glacial lake information. The objectives of this study are as follows: (1) planning a U-Net network to extract large-scale glacial lake information from the combination of 3, 5 and 6 bands and all bands of Landsat-8 remote sensing images, (2) developing a self-attention U-Net network framework to

improve glacial lake extraction performance and accuracy and (3) extracting glacial lake information from Landsat-8 images in 2018 based on the self-attention U-Net network. This study provides a supporting method for rapid and intelligent monitoring of glacial lake information along the Sichuan-Tibet railway.

The rest of this paper is organised as follows. Section II describes the study area, Section III describes the U-Net and self-attention U-Net network model, Section IV presents results and analysis and Section V concludes the paper.

II. STUDY AREA

The Alatau mountains of Tianshan was selected as the study area. Alatau mountain belongs to the Tianshan mountain system, which is located in the north of the Bortala Mongol autonomous prefecture in Xinjiang ($79^{\circ}30' - 81^{\circ}45'E$, $44^{\circ}40' - 45^{\circ}20' N$). The mountain runs from east to west, and its northern slope is in the Republic of Kazakhstan. The snow line is low, at 3500 m. At 3800 m there are mainly suspended glacial and bucket glacial lakes, most of which are distributed in the north. The end drops to 3300 m above sea level, the ridge elevation is 4000 m, and the highest peak is 4570 m. The annual precipitation in the alpine belt can reach 1000 mm. The north side, in Kazakhstan, is moist, with the snow line below 3600 m. The south side, in China, is dry, and the snow line can rise to 3900 m. About 2/3 glacial lakes are distributed in the north side of Kazakhstan. In recent years, many small glacial lakes have developed, of various types and with rich characteristics [33]. The study area is shown in Figure 1.

III. METHODOLOGY

A number of Landsat-8 images were first selected and embedded into the study area. Then, each band image was cut into chunks to construct a data set. Then, U-Net and improved U-net (self-attention U-Net) networks were used to extract glacial lakes, which are depicted in Figure 2. Kappa coefficient, F1-score, Mean Intersection over Union (MIoU) and Area Under Curve (AUC) were used for evaluation. The following sub-sections provide more details on individual aspects of the methodology.

A. Data source

This research selects Landsat-8 satellite remote sensing data (orbit number 147028, 147029, 148029) in 2018 (<https://www.usgs.gov>). Landsat-8 data include eleven bands, and the specific sensor parameters are shown in Table 1. Firstly, the remote sensing image is preprocessed in ENVI software, including atmospheric correction, geometric correction and radiation calibration, then the band layers are superimposed together, and the multi-scene image is embedded to make it become the whole multi-spectral image of the study area. All eleven bands were selected for the experiment in this study. The spatial resolution of two bands in Landsat-8 TIRS is 100 m, and we resampled them to the same resolution as the other bands (30m). Normalized differential water index (NDWI) and normalized differential snow index (NDSI) are classic methods

to extract water. The 3, 5 and 6 band used is sensitive to water, so this experiment also tries to combine 3, 5 and 6 band to extract the information of the glacial lake to improve efficiency.

B. Data set construction

(1) Ground truth: accurate glacial lake boundary information

in the study area was extracted by visual interpretation of Google Earth images, and was converted into a binary image as the ground truth for samples, in which the foreground (white) represents glacial lake areas and the background (black) represents non-glacial lake areas (as shown in Figure 3).

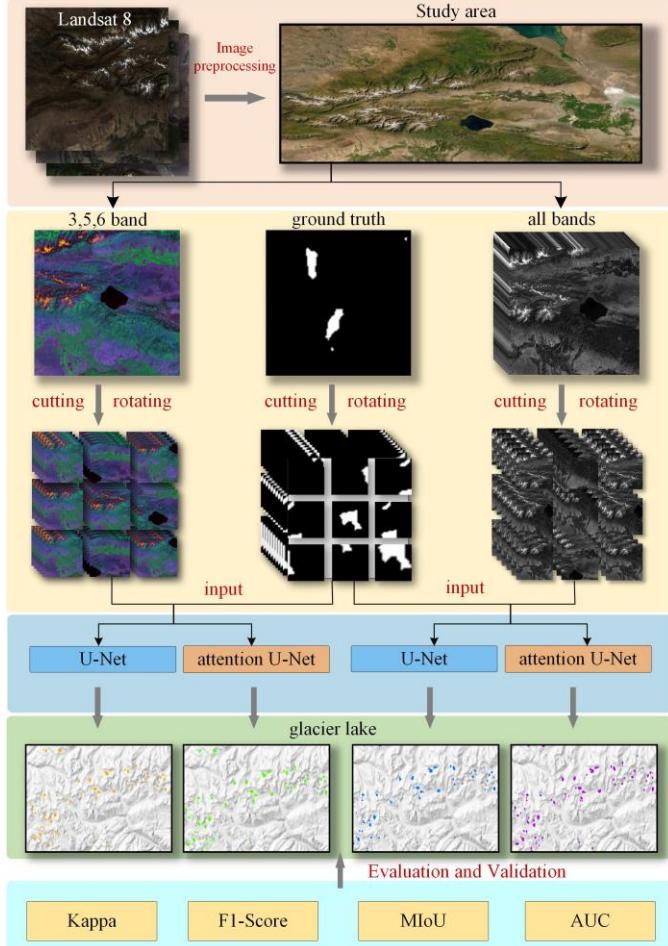

Fig. 2. Glacial lake extraction flow chart

(2) Training data: Remote sensing images (the combination of 3, 5 and 6 bands and all bands) were cut and enlarged. The cutting method: define three scaling ratios, which are 1, 2, 4, and the output image size is 256×256 , 128×128 , 64×64 . In the 256×256 size cutting, we adopted the overlapping cutting strategy with a step size of 128. Therefore, most areas with glacial lakes were trained 2-4 times in the neural network, and they were all at different positions of the image after cutting. The overlapping strategy was not adopted in the cutting of 128×128 and 64×64 sizes, because when the data set was resized to 256×256 , the distortion of too much scaled data would affect the precision of network training. Augmentation method: mirror and rotate (rot 90) the original image. The output image should contain not only the original glacial image, but also the image that mirrors and rotates (rot 90) the original image in order to enrich the training data. The same operation is carried out on the ground truth to get a data pair with the processed images. In order to simplify the training data set, the images without glacial image are excluded from the data set.

(3) Data set: the training image and ground truth were read separately according to the following path: each time, the image and the corresponding label were scaled to 256×256 and normalised; the proportion of training set : test set : verification set was set to 8:1:1, uniform sampling. Finally, 2553 training

samples, 320 verification samples and 320 test samples were generated. Figure 3 shows some representative samples in the data set formed after sample segmentation.

C. U-Net network

A U-Net network is a U-shaped network structure, which can obtain context and location information at the same time. Its design was originally intended to solve the problem of medical image semantic segmentation [34]. U-Net is a more refined design based on the basic structure of a full convolution neural network (FCN) and it is also more efficient, replacing optimised FCN networks. It is mainly composed of an encoder, decoder and skip connection [34],[35]-[36]. The encoder is used to extract spatial features from images and reduce spatial dimensions. It divides the feature map into five scales, each of which contains two convolution layers with the same number of output channels and 3×3 convolution kernel size and is connected by a maximum pool with a step size of 2. Through scale-by-scale convolution sampling, features of different dimensions are extracted and retained from the context of the feature map. It is composed of two 3×3 convolution layers (ReLU) and 2×2 max pooling layers (stride is 2). After each down-sampling, the number of channels is doubled, and the last two 3×3 convolution operations connect the encoder to the decoder. The convolution layer is used to extract image features, and the lower sampling layer is used to filter unimportant high frequency information, reduce the feature dimensions and increase the receptive field. Repeated convolution and pooling operations can fully extract the high level features of the remote sensing image. The decoder is used to construct a segmentation map according to encoder features to gradually restore the details and spatial dimensions of the remote sensing image. In the decoder, the scale division of the feature map is partially symmetrical with that of the encoder, and the feature extraction part of each scale is composed of two 3×3 convolution layers with the same number of output channels. Each scale is also connected to an upper sampling layer of size 2 and a convolution layer with a convolution kernel size of 2×2 . Finally, the 1×1 convolution layer returns to the pixel classification, and the input of each decoding block is fused with the output of the corresponding layer coding block as the input of the next deconvolution layer, so as to reduce the information loss caused by down-sampling in the coding block. The problem of glacial lake extraction belongs to two categories, but there is only one output channel. Skip connection transfers the output from encoder to decoder, in series with the output of the up-sampling operation, and propagates the cascade feature map to subsequent layers to retain as much detail as possible and improve the resolution and edge accuracy of the final segmentation result. Padding of all convolutional layers is set to the size of output feature graph consistent with the input, that is, "Same" mode is used, which has little impact on segmentation accuracy in classification task, and is easy to make datasets and handle subsequent parts. In this study, U-Net is used as the basic network for the glacial lake boundary information extraction model, the structure of which is shown in Figure 4.

IEEE JOURNAL OF SELECTED TOPICS IN APPLIED EARTH OBSERVATIONS AND REMOTE SENSING

D. U-Net network based on self-attention mechanism

Remote sensing image data contains various kinds of complex feature information, such as glaciers, vegetation, bare land and mountain shadows. In this study, only glacial lake features are extracted, and other features are used as background processing. The complex background greatly interferes with the accuracy of glacial lake extraction [37]. The attention mechanism is designed to selectively ignore part of

the information to carry out the weighted aggregate calculation of the rest of the information. Its basic function is to highlight a core part of the feature map to become the input of the attention feature, so that the model pays more attention to the relevant information [38]. Therefore, this study proposes to introduce the attention mechanism into the step connection part of the U-Net network to adjust the feature weight, focus on learning glacial lake features, and strengthen the network for extracting

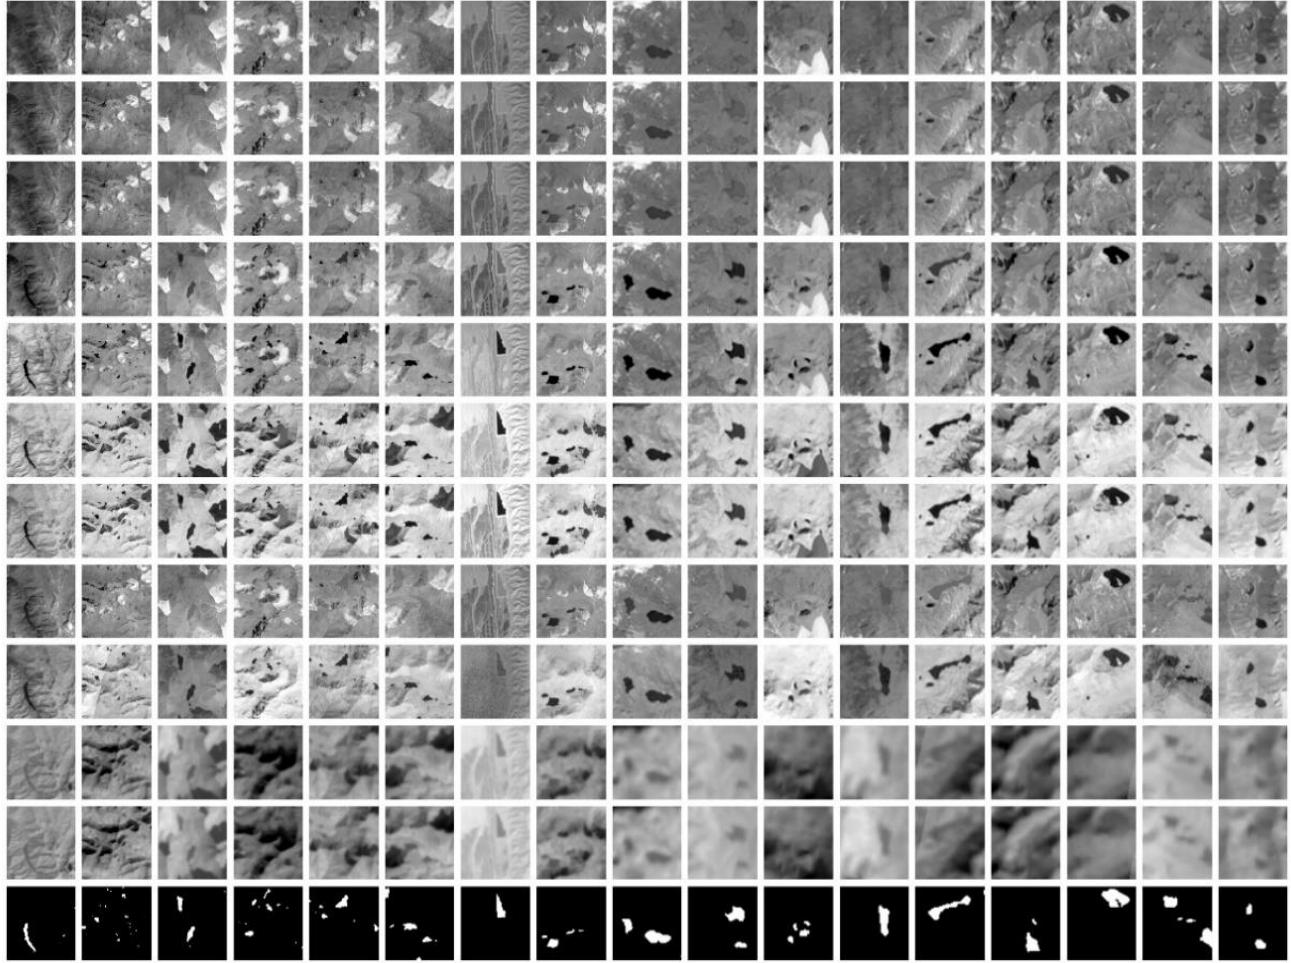

Fig. 3. Sample of partial dataset after sample segmentation (all bands, ground truth)

glacial lake features.

A structural diagram of the attention gate (AG) is shown in Figure 5, where g is the feature map matrix of the decoding part and x is the feature map matrix of the coding part. The self-attention U-Net network structure is shown in Figure 6. The encoder and decoder parts use the same scale, which is connected to the AG module to realise the attention mechanism. First, the AG module carries out a 3×3 convolution operation by combining the feature map of the same scale as the encoder part with the result of the upper sampling from the decoder part, with the number of output channels being half that of the scale encoder and decoder parts, so as to extract the fused features on a coarse scale while eliminating irrelevant noise. ReLU has an activation function to suppress over-fitting from the AG module [39]. Then the convolution layer with 1 output channel and 1×1

convolution kernel size is used to output the attention weight matrix, and a sigmoid function is selected as the activation function to output the normalised weight index. Sigmoid functions are used as a regression classification method for dichotomy problems [28]. By multiplying the normalised attention weight matrix and the fusion result of the first step of the AG module, the feature fusion result with attention weight is obtained. Finally, the result is fused with the result of the 2×2 convolution after partial up-sampling from the decoder. The AG mechanism not only satisfies the multi-scale feature fusion in semantic segmentation, but also solves the traditional U-Net deficiency of fixed weights in the same scale skip connection. Padding of all convolutional layers is set to the “Same” model, that is, the size of output feature map is set to be consistent with the input.

The specific operations of the self-attention mechanism are

as follows:

Feature weight extraction:

$$W_{concat(x,g)} = \frac{1}{H \times W} \sum_{i=1}^H \sum_{j=1}^W f(i,j) \quad (1)$$

where, g is the feature map matrix of the decoding part, x is the feature map matrix of the encoding part, H and W represent the length and width of the feature map, respectively, $W_{concat(x,g)}$ is the feature weight matrix, and i and j correspond to the position of pixels in the feature map.

By combining the feature map x of the encoding part and the feature map g of the decoding part by formula (1), the weight matrix of the feature map $W_{concat(x,g)}$ is obtained.

Feature weight update:

$$q_{att} = ReLU(W_{concat(x,g)}) \quad (2)$$

$$\alpha = Sigmoid(q_{att}(W_{concat(x,g)}; \Theta_{att})) \quad (3)$$

Where $ReLU$ is the activation function. Θ_{att} is a set of parameter linear transformations and bias terms.

E. Training model

FCN network computing is calculation-intensive and consumes a lot of video memory during training, which requires high-level hardware. If limited by the preglacial and experimental environment, it will pursue a balance in the platform. The model of this paper is based on the deep learning framework Keras. The deep learning experimental environment is built according to the current mainstream configuration environment. The basic configuration is shown in Table 2.

The important software configuration for this study is shown in Table 3. According to the operation of each model, the reference can install the corresponding software package appropriately to speed up the operation of the model [40].

When the batch size is set to 8, the convergence rate of a large batch size is lower than that of a small batch size with the same limited capacity for computation. A too-large batch size may

make the neural network non-convex, and there may be multiple local optimal or saddle points, that is, the eigenvalues of the corresponding Hesse matrix are both positive and negative. Therefore, in practical engineering, a small batch of sample set mini-batches is optimal from the point of view of convergence speed, and the batch size often varies from tens to hundreds, but generally no more than a thousand. Here, due to hardware limitations of video memory, the batch size is set to 8.

Considering the computational efficiency of the model, the hardware capacity and the desired accuracy of the results, the number of iterations over the course of the experiment was set to 128. Adaptive moment estimation ('Adam') was selected as the optimiser [41]. The Adam algorithm is equivalent to a combination of the Rmsprop gradient descent and momentum gradient descent methods. It has high convergence speed, good learning effect and is suitable for all kinds of neural networks. The learning rate was set to 10^{-4} . The binary cross-entropy (BCE) is selected as the loss function. The target of the neural network in this paper is the binary classification problem. When the BCE is used as the loss function, the gradient of the final output layer has nothing to do with the derivative of the activation function, but is only proportional to the difference between the output value and the real value. Therefore, when the model approaches the real value, the gradient remains at a high state and the convergence speed of the model remains fast. After iterative training over the whole study area, the network finally converged.

The BCE loss function of the second classification was arrived at as follows. There are only positive and negative examples in the second classification, and the probability sum of the two is 1, so there is no need to predict a vector; therefore, only one probability is needed. The definition of the loss function is as follows:

$$BCE(x)_i = -\sum_{i=0}^n (y_i \log \hat{y}_i + (1 - y_i) \log(1 - \hat{y}_i))/2 \quad (4)$$

Where y^{\wedge} examples is the probability that the model predicts that the sample is a positive example, and y is the sample label, if the sample belongs to a positive example, the value is 1, otherwise the value is 0.

F. Evaluation index

To quantitatively evaluate the performance of the glacial lake boundary information extraction model, the following indicators were used to evaluate its accuracy: kappa coefficient, precision rate (P), recall rate (R), F1-score (F1), Mean Intersection over Union (MIoU) and Area Under Curve (AUC). When comparing the extraction results, the following four pixel evaluation categories were considered, and several indicators were calculated directly from the confusion matrix, as shown in Table 4.

Kappa coefficient:

$$Kappa = \frac{N \sum_{i=1}^n X_{ii} - \sum_{i=1}^n (X_{ii} + X_{+i})}{N^2 - \sum_{i=1}^n (X_{ii} + X_{+i})} \quad (5)$$

Where n is the total number of columns in the confusion matrix (the total number of categories); X_{ii} is the number of

samples in the i row and i column of the confusion matrix, that is, the number of samples correctly classified; X_{+i} and X_{i+} are the total number of samples in row i and column i, respectively; N is the total number of samples used for accuracy evaluation.

Precision Rate (P):

$$P = \frac{TP}{TP+FP} \quad (6)$$

Recall Rate (R):

$$R = \frac{TP}{TP+FN} \quad (7)$$

F1-score (F1) is the harmonic average of precision P and recall R:

TABLE 4
ACCURACY EVALUATION CONFUSION MATRIX

Confusion Matrix	Prediction	
	True	False
Ground truth	True Positive TP	False Negative FN
	False Positive FP	True Negative TN

$$F1 = 2 \times \frac{P \times R}{P+R} \quad (8)$$

Mean Intersection over Union (MIoU), for the binary classification problem:

$$MIoU = \frac{\frac{TP}{FP+TP+FN} + \frac{TN}{FP+TN+FN}}{2} \quad (9)$$

Area Under Curve (AUC):

$$AUC = \frac{\sum_{ins_i \in positive class} rank_{ins_i} - \frac{M \times (M+1)}{2}}{M \times N} \quad (10)$$

Where $rank_{ins_i}$ represents the serial number of the sample in Article i, that is, the probability score is ranked from small to large, ranking in the rank. M and N are the number of positive samples and negative samples, respectively. $\sum_{ins_i \in positive class} rank_{ins_i}$ means that only the rank sequence numbers of the positive samples are added.

IV. RESULTS AND ANALYSIS

In this study, U-Net and self-attention U-Net network models were used to extract large-scale glacial lake in the Alatau mountains based on a Landsat-8 remote sensing image. The extraction results are shown in Figure 7a.

A. Accuracy analysis of glacial lake extraction results

From the comparison and analysis of the segmentation result map and ground truth in subjective evaluation (Figure 7), the U-Net network accurately extracted the boundary information of a large range of glacial lakes based on the combination of 3, 5 and 6 bands and all bands of Landsat-8 in a complex mountain environment, and at the same time remove the influence of

mountain shadows (Figure 7b, c), which reflects the general ability and time-space expansion of the U-Net network. The 3, 5 and 6 bands of Landsat-8 image are sensitive to water body, while glacial lake is a special kind of water body, so it is necessary to extract glacial lake with the combination of 3, 5 and 6 bands. It is also found that the combination of 3, 5 and 6 bands can better extract the glacial lake. The self-attention U-Net network can more accurately extract glacial lake boundary information (Figure 7d, e). Compared with the U-Net network, the range of glacial lake boundary extracted using the self-attention U-Net network is larger and closer to the ground truth (Figure 7f). However, in the segmentation result map, the U-Net network cannot segment information well from a small glacial lake. There are many omissions, and the boundary segmentation is coarse (Figure 7b, c, red ellipse), but the hillshade can be distinguished better (Figure 7). For small glacial lakes, the self-attention U-Net network can extract the boundary more accurately. Especially when the input data is from all bands, the extraction result of the self-attention U-Net network can be closer to the ground truth. This may be because the spectral characteristics of texture and geometry features for all bands are more abundant.

The extracted results were further analysed to reveal the effectiveness of the new method. In order to compare the results of the extraction of glacial lakes more clearly, this study selected some typical areas and superimposed the extracted glacial lake boundary information on the Landsat-8 remote sensing images to reveal the accuracy at different scales (Figure 8). In Figure 8, the first column (Figure 8a) is the original Landsat-8 image, the second column (Figure 8b) is the ground truth, the third column (Figure 8c) is the U-Net network

IEEE JOURNAL OF SELECTED TOPICS IN APPLIED EARTH OBSERVATIONS AND REMOTE SENSING

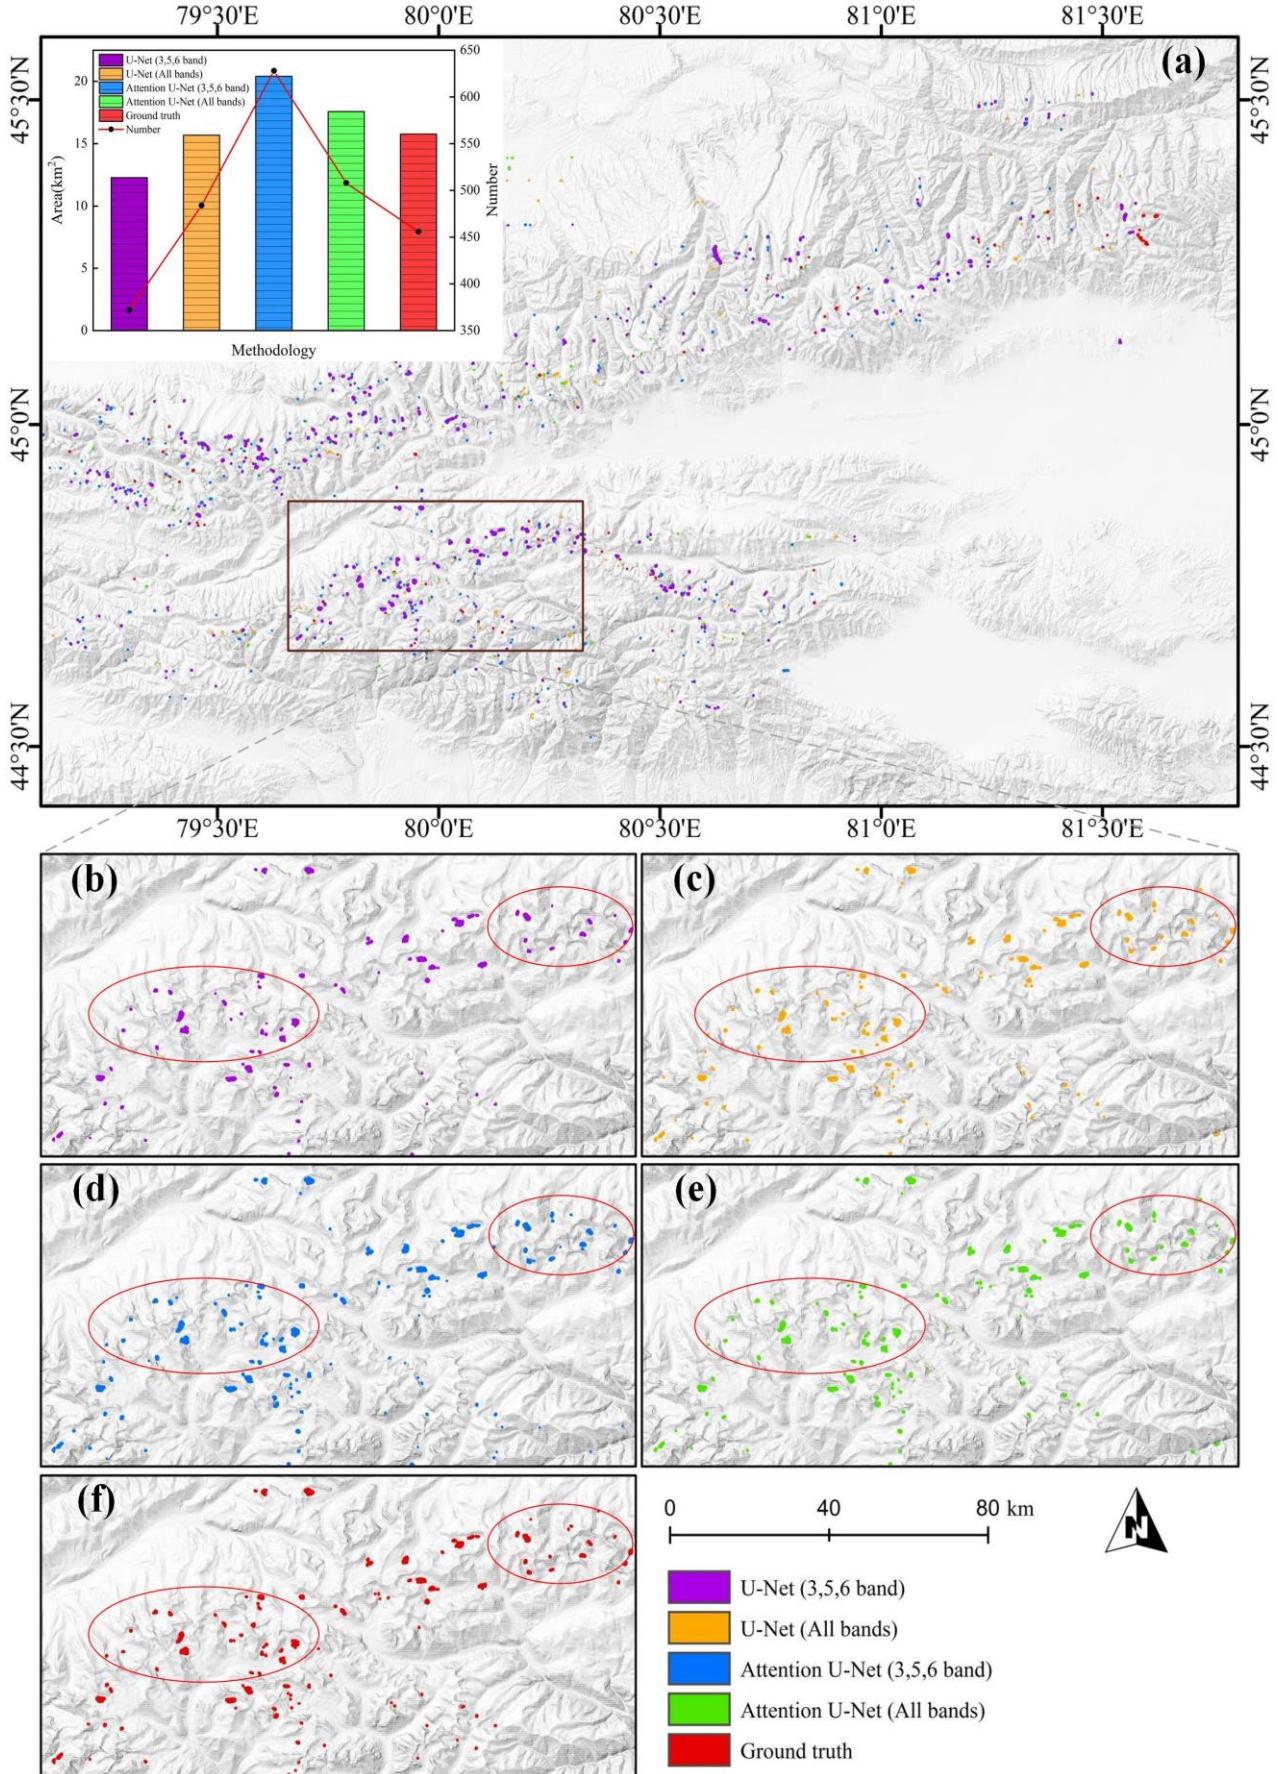

Fig. 7. Glacier lake extraction results based on U-Net and attention U-Net network

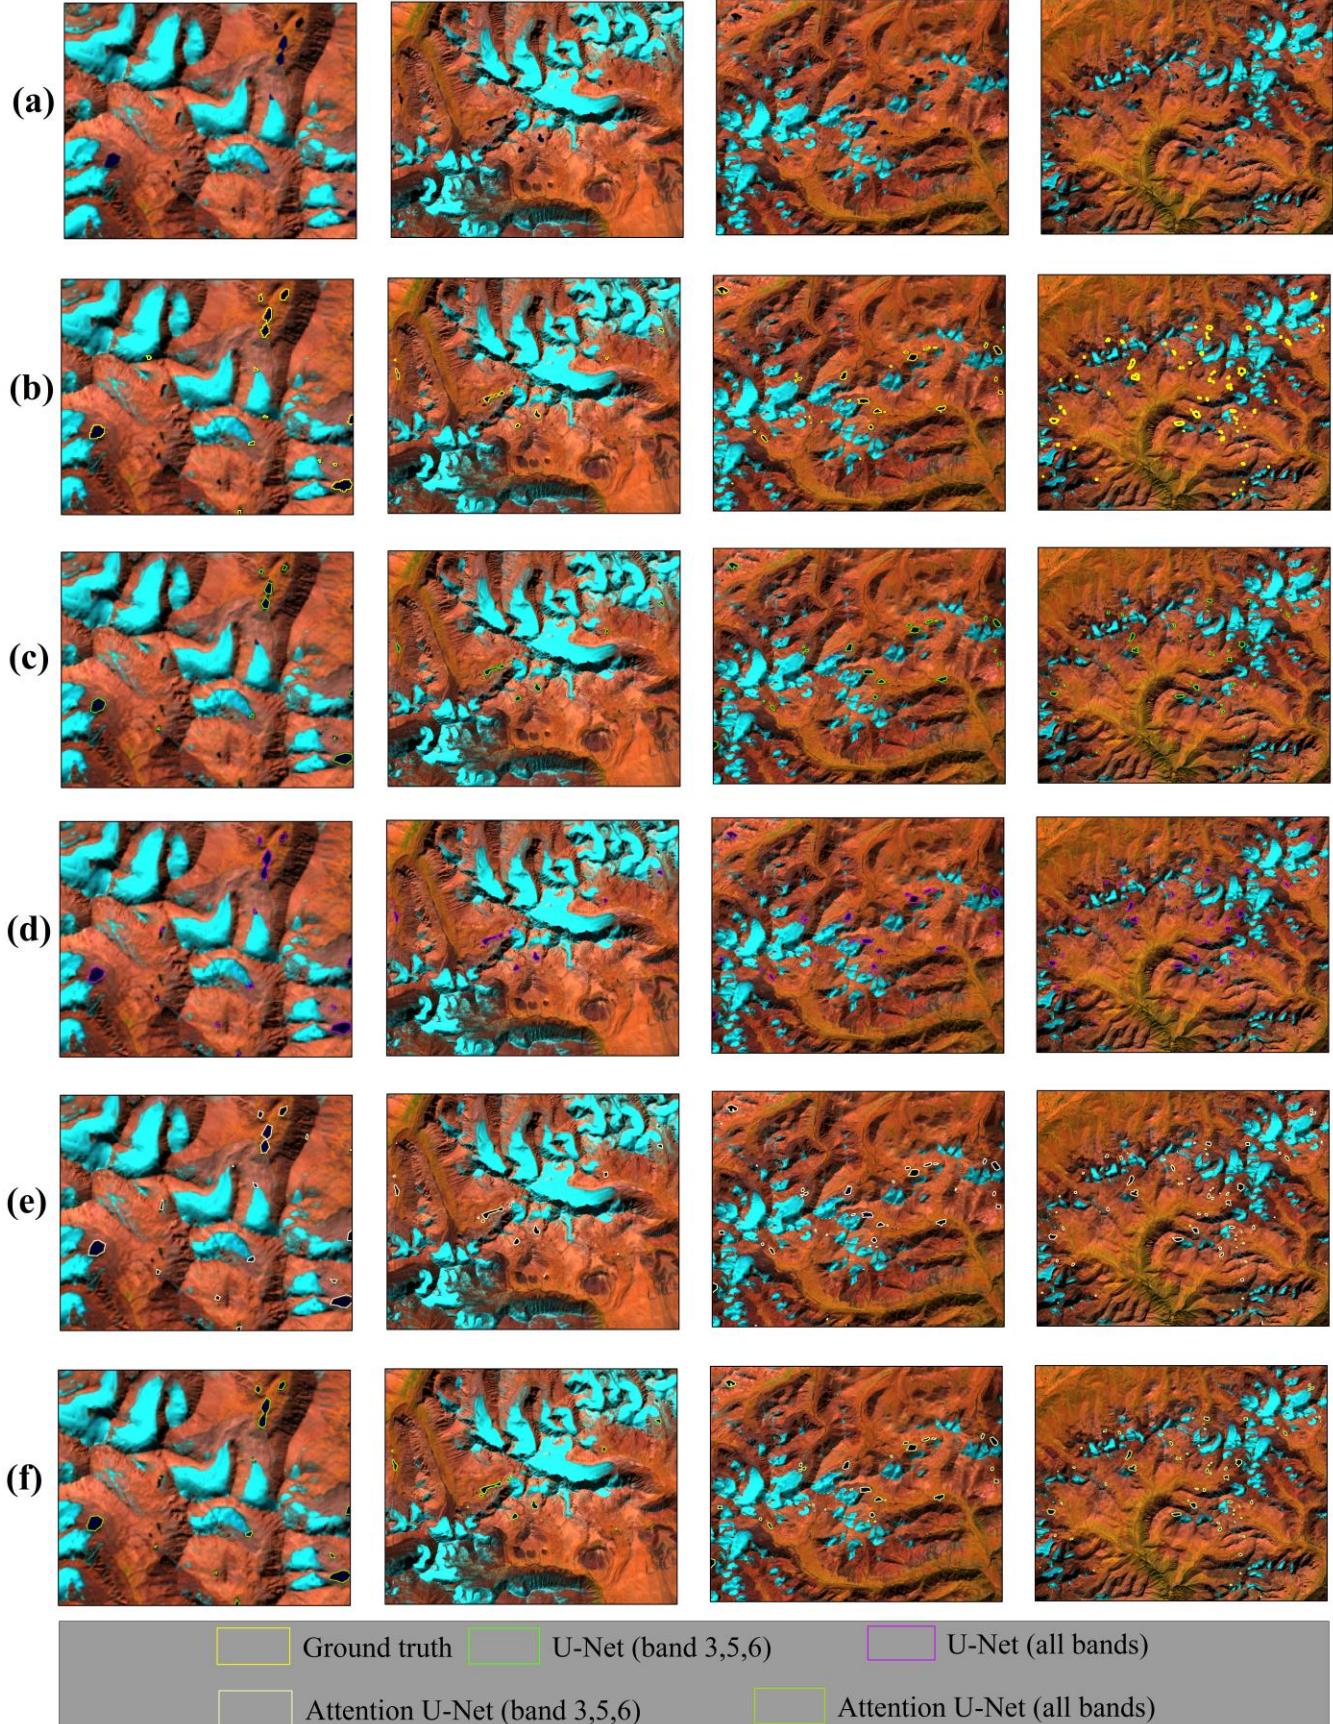

Fig. 8. Comparison of glacial lakes extraction results with different methods in typical areas of the study area. (a)Landsat-8 images, (b)ground truth, (c)U-Net (3,5 and 6 bands), (d)self-attention U-Net (3,5 and 6 bands),(e) U-Net (all bands), (f) self-attention U-Net (all bands)

segmentation result map for the 3, 5 and 6 band combination, the fourth column (Figure 8d) is the U-Net network segmentation result map for all bands, the fifth column (Figure 8e) is the self-attention U-Net network segmentation result map for the combination of 3, 5 and 6 band and the sixth column (Figure 8f) is the self-attention U-Net network segmentation result map for all bands.

As can be seen in Figure 8, self-attention U-Net network segmentation of the glacial lake boundary is more obvious, and the segmentation result similar to the segmentation ground truth can be obtained. The small glacial lake is segmented well and missed detections are relatively few. The influence of shadows can be removed at the same time, but surrounding features will be excessively extracted. In general, the self-attention U-Net network can effectively combine low-dimensional and high-dimensional feature information from an image. While digging the deep law of the image, it retains the low-dimensional feature information of the image and finds features that effectively distinguish the glacial lake from other ground objects.

As can be seen in Figure 9, the training results of the self-attention U-Net network in the binary graph of the training model have more abundant information (red circle) than that of the U-Net network for the combination of 3, 5 and 6 bands and all bands, while the training results of all bands are better than the combination of 3, 5 and 6 bands. Because all bands has more information, and most of bands are related to the features of glacial lake, so the input of all bands into the neural network can assist the extraction of the spectral and texture features of glacial lake. It can be seen from Figure 9e and Figure 9f that the manual labels were omitted. However, due to the redundant information of all bands and the fault tolerance of the network,

some missing labels are also identified during the input of all bands. This shows that using all bands for the dataset can improve classification accuracy.

B. Analysis of the glacial lake extraction performance

As can be seen from Figure 10, the pixel accuracy of both the U-Net and self-attention U-Net network models in the initial stage of training is low. Both show high growth at the 30th epoch, after which there is little change. The U-Net network model fluctuates and the self-attention U-Net network model is relatively stable, indicating that the performance of the self-attention U-Net network has been greatly improved. The U-Net network and self-attention U-Net network achieved about 80% classification accuracy in the training set of the combination of 3, 5 and 6 bands and all bands (11 bands), and 90% classification accuracy in the test set, respectively, but on the whole, the training process of the self-attention U-Net network model is stable. The classification accuracy of the self-attention U-Net network model in all bands was the highest. The loss rate during model training is very low. This suggests that the self-attention U-Net network has good performance in glacial lake extraction.

In order to further quantitatively analyse the performance and extraction accuracy of the two models, the model performance was evaluated using the confusion matrix, Kappa coefficient, F1-Score, MIoU and AUC. The results of these evaluation indicators are presented in Figure 11. Using the U-Net network, the true positive (TP) for the combination of 3, 5 and 6 band and all bands was 59.45% and 72.90% (Figure 11a, b), respectively, while for the self-attention U-Net network the TP was 75.40% and 78.69% (Figure 11c, d), respectively.

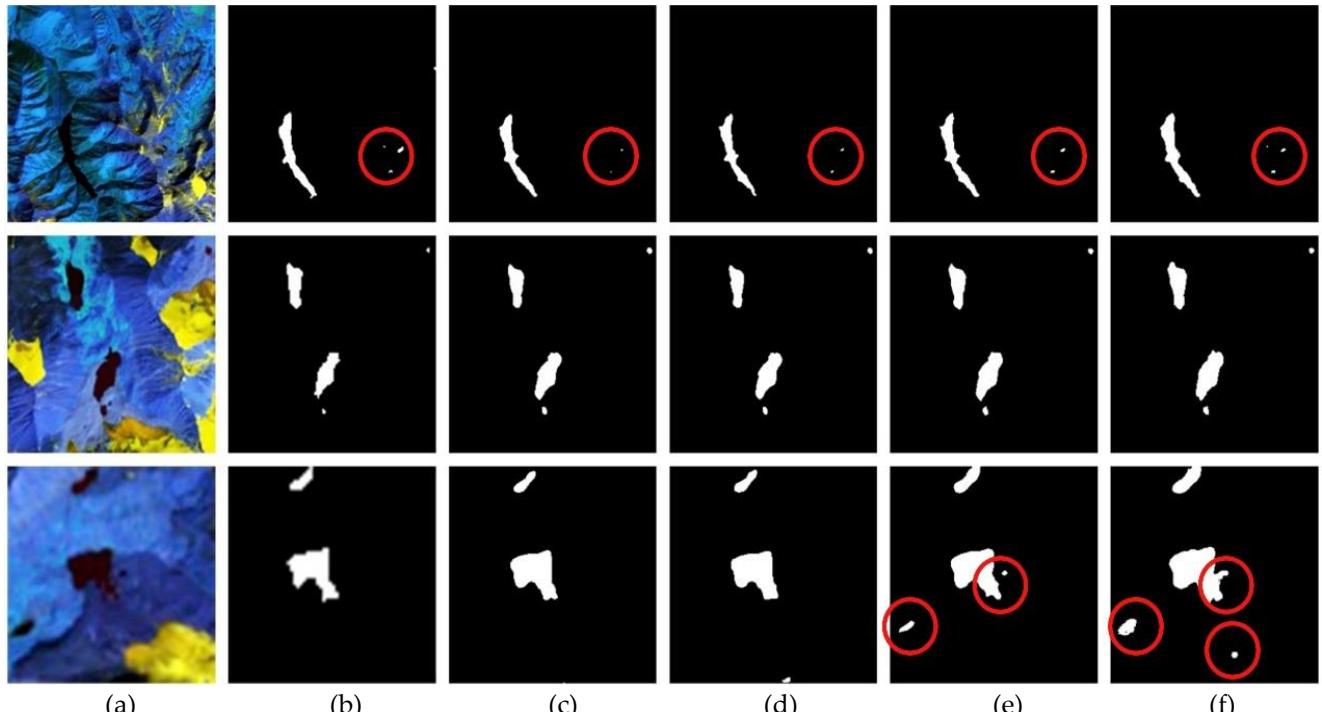

Fig. 9. Comparison of model training results. (a) remote sensing images, (b) ground truth, (c) U-Net (3,5 and 6 bands), (d)self-attention U-Net (3,5 and 6 bands),(e) U-Net (all bands), (f) self-attention U-Net (all bands)

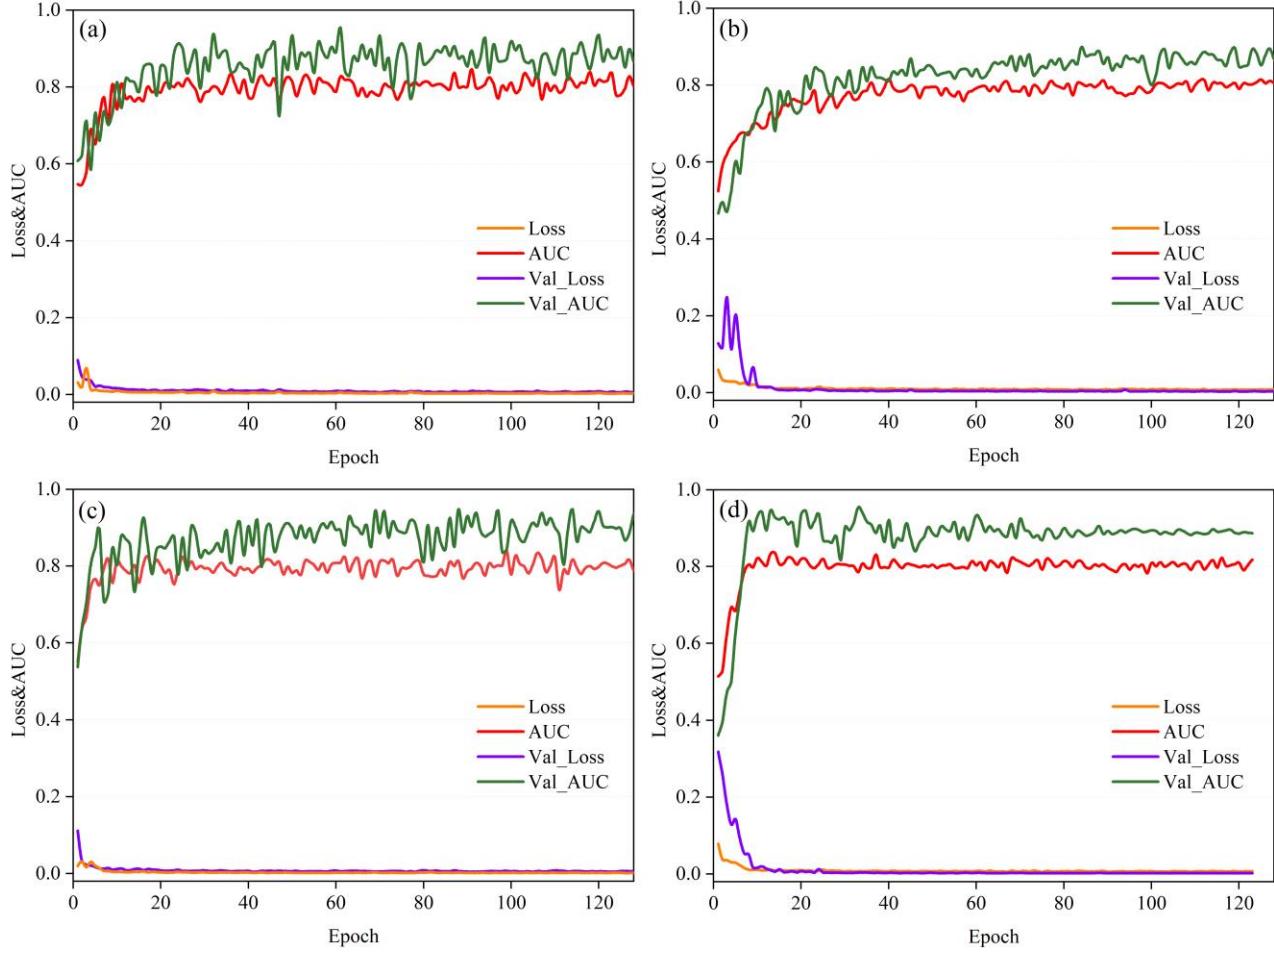

Fig. 10. U-Net and attention U-Net model training and testing curve (a) U-Net (3,5,6 band),(b)attention U-Net (3,5,6 band),(c) U-Net (all bands), (d) attention U-Net (all bands)

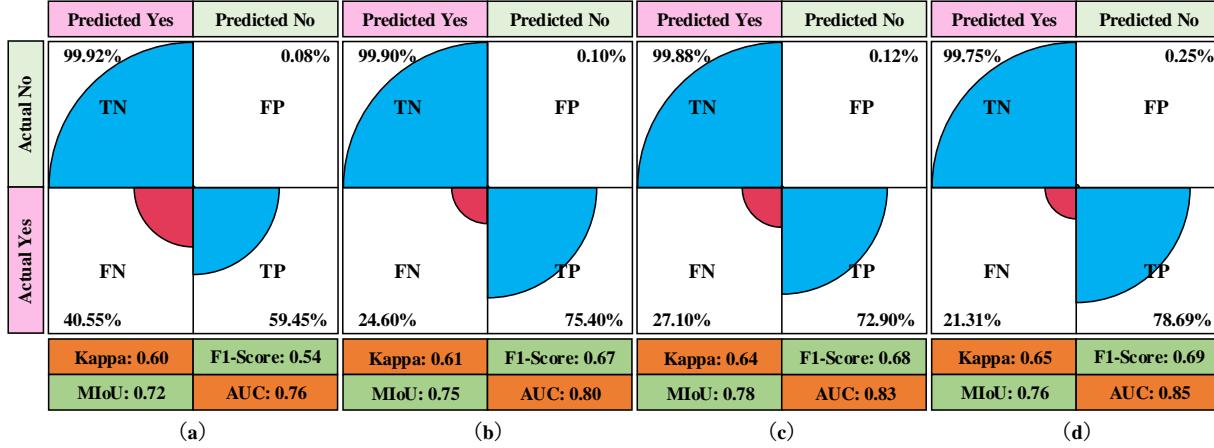

Fig. 11. Performance of extraction models trained on glacier lake inventories by confusion matrix, Kappa coefficient, F1-Score, Mean Intersection over Union (MIoU) and area under the ROC curve (AUC). (a) U-Net (3, 5 and 6 bands), (b) attention U-Net (3,5 and 6 bands),(c) U-Net (all bands), (d) attention U-Net (all bands)

For the combination of 3, 5 and 6 bands and all bands, the true positive (TP) increased by 15.95% and 5.79%, respectively, compared to the U-Net network. MIoU using the self-attention U-Net network reached 0.75 and 0.76, respectively (Figure 11b, d). In the entire large-scale research area, AUC for the combination of 3, 5 and 6 bands using the self-attention U-Net

network reached 80%, which is 4% higher than the U-Net network model (Figure 11a, b). For all bands, all index values of U-Net and the self-attention U-Net network model are higher than the combination of 3, 5 and 6 bands.

For the whole study area, the AUC based on the self-attention U-Net network model can reach 0.85 (Figure 11d), suggesting

IEEE JOURNAL OF SELECTED TOPICS IN APPLIED EARTH OBSERVATIONS AND REMOTE SENSING

that it is effective and feasible as a method for extracting glacial lakes and has good predictive performance. The self-attention U-Net network model suppresses the weight of non-icy-lake features, slows down the impact of low image contrast on the model, suppresses the problem of pixel category imbalance and improves the performance of the model, especially in its accuracy given all bands of data.

From the above analysis, it can be seen that the self-attention U-Net network model can alleviate the problems of missed and false detections in low-contrast areas and small glacial lakes under complex backgrounds. The general ability of the network model is relatively good. Therefore, the improved U-Net network model can more accurately extract boundary information of glacial lakes in high mountains. The extraction method of glacial lakes in this study can provide a new technology for rapid extraction of glacial lake disasters on the Sichuan-Tibet Railway.

V. CONCLUSION AND OUTLOOK

The proposed method applies remote sensing datasets for accurate extraction of glacial lakes. At present, existing glacial lake extraction algorithms lack the ability to analyse glacial lake spectra and shape and texture features, and require manual design parameters to fine-tune the automation of the algorithm. As a result, it cannot mine depth features of glacier lakes in remote sensing images accurately enough. In the presented study, we introduced the attention mechanism into the step connection part of the U-Net network to adjust feature weight, focus on learning glacial lake features and strengthen the network to extract the glacial lake features. The attention U-Net network model enhances the propagation of features, reduces information loss, strengthens the weight of the glacial lake areas, restrains the weight of irrelevant features, reduces the influence of low image contrast on the model and deals with variety of pixel categories in glacial lakes. These features improve the performance of the model. The effectiveness of this new method was proved by different evaluation indices. Area under curve (AUC) for the whole study area reached 85.03% for all bands of the Landsat-8 images, which can thus meet the real-time demands of large-scale glacial lake disaster information acquisition. Thus, we can obtain a more reliable glacial lake extraction model. This study obtained a large-scale glacial lake data set (2018) in the Alatau mountains of the Tianshan to provide data support for subsequent research on glacial lake disasters in the Tianshan mountains.

In follow-up work, more types of remote sensing images can be collected to effectively monitor high mountain glacial lakes in a timely manner. In the training data, the number of samples under different background features should be increased to enhance the general ability of the model. Therefore, the next step of the research work will focus on strengthening the extraction of glacial lakes under different background ground features, and further improve the temporal and spatial scalability of the model.

ACKNOWLEDGMENT

The authors would like to thank the editors and anonymous reviewers for their valuable suggestions, and thank the Geospatial Data Cloud for providing access to the orthorectified Landsat imagery.

Yi He received the B.S. in geographic information system from Lanzhou Jiaotong University, Lanzhou, China, in 2011, and the Ph.D. degree in earth system science from Lanzhou University, China, in 2016. He has been a Postdoctoral Researcher with the school of environment and municipal engineering, Lanzhou Jiaotong University, Lanzhou, China. He is currently a associate professor with the faculty of geomatics, Lanzhou Jiaotong University, Lanzhou, China.

His research interests include disaster remote sensing, ecological remote sensing, image processing and time series InSAR prediction based on deep learning.

Sheng Yao received the B.E. degree in digital media technology from the North China University of Technology, Beijing, China, in 2020. He is currently working toward the M.S. degree at faculty of geomatics, Lanzhou Jiaotong University, Lanzhou, China.

His research interests include application of remote sensing in deep learning.

Wang Yang received the B.E. degree in Remote sensing science and technology from the Lanzhou Jiaotong University, Lanzhou, China, in 2019. He is currently working toward the M.S. degree at the faculty of geomatics, Lanzhou Jiaotong University, Lanzhou, China.

His research interests include InSAR data processing technology, machine learning and remote sensing image information extraction.

Haowen Yan received Ph.D. degree in cartography and geographical information engineering from Wuhan University, Wuhan, China in 2002, and Ph.D. degree from Waterloo University, Canada in 2014. He is a Editor-in-Chief of Journal of Geo-visualization and Spatial Analysis. He is the dean of the faculty of geomatics of Lanzhou Jiaotong University and the director of the

IEEE JOURNAL OF SELECTED TOPICS IN APPLIED EARTH OBSERVATIONS AND REMOTE SENSING

National-Local Joint Engineering Research Center of Technologies and Applications for National Geographic State Monitoring, Lanzhou.

His research interests include WeMaps, automated map generalization, spatial relations, geovisualization and spatial analysis, spatial data finger-printing and watermarking, history of maps and cartography.

Lifeng Zhang received the M.S. degree in cartography and geographic information system from Lanzhou Jiaotong University, Lanzhou, China, in 2010, and a Ph.D. degree in environmental science and engineering from Lanzhou Jiaotong University, Lanzhou, China in 2017. He is a associate professor, Lanzhou Jiaotong University, Lanzhou, China.

His research interests include ecological environment remote sensing monitoring, visualized analysis, and analysis of land use change.

Zhiqing Wen received the B.E. degree in surveying and mapping engineering form the Chang'an University, Xian, China, in 2020. He is currently working toward the M.S. degree at faculty of geomatics, Lanzhou Jiaotong University, Lanzhou, China.

His research interests include remote sensing image processing and remote

sensing application.

Yali Zhang received the B.E. degree in remote sensing science and technology from the Lanzhou Jiaotong University, Lanzhou, China, in 2020. She is currently working toward the M.S. degree at the faculty of geomatics,Lanzhou Jiaotong University, Lanzhou, China.

Her research interests include InSAR data processing technology, extraction of glacier movement velocity and remote sensing image fusion.

Tao Liu received Ph.D. in cartography and geographical information engineering from Wuhan University, Wuhan, China in 2011. He is currently professor with the faculty of geomatics, Lanzhou Jiaotong University, Lanzhou, China. He is a member of the theory and method work committee of China geographic information industry association.

His research interests include spatial relation theory, GIS and RS integration and application and development of GIS and RS.
